Clinical efficiency of aerobic exercises in the young patients with type 1 diabetes mellitus

Abstract. Background. The purpose of the study is to investigate the effect of regular aerobic physical exercises with 6-point intensity by Borg scale on glycemic profile, insulin sensitivity, and quality of life of patients with type 1 diabetes mellitus (DM). Materials and methods. The data from 42 patients with type 1 DM were analyzed. There were 20 women and 22 men aged 18 to 35 years (mean age 25.3 ± 7.9 years). The level of glycemia and glycated hemoglobin was estimated. The Medical Outcomes Study Short Form 36 questionnaire was used to assess the quality of life. Results. It has been shown that aerobic exercises can significantly modify the clinical course of type 1 DM and change the quality of life. After 30 days of regular aerobic exercises, the mean daily dose of ultra-short-acting insulin was decreased by 25.4 % versus baseline (p < 0.05). It was found that sensitivity to insulin after regular aerobic exercises was increased by 42.0 % and became 0.60 U per 1 bread unit (BU) by the end of the observation versus 1.03 U per 1 BU before the study. Also, regular physical activity was associated with the decrease in glycated hemoglobin content by 1.5 %. It has been established that regular aerobic exercises contributed to the significant (p < 0.05) increase in the quality of life according to all the scales which form physical and psychological components of health (physical functioning, role-physical functioning, bodily pain, general health, role-emotional functioning, vitality, mental health, social functioning) versus baseline that was accompanied by increase in emotional stability and workability. Conclusions. Regular aerobic exercises had the positive impact on the clinical symptoms of type 1 DM, resulted in improved glycemic profile, increased insulin sensitivity and quality of life of patients.

Keywords: type 1 diabetes mellitus; aerobic exercises; glycemic profile; insulin sensitivity; quality of life
and effort from the patients, therefore, it could not be represented in the clinical practice.

At the same time, the question of possibility and effectiveness of physical exercises, its impact on the DM management, and the way the regular physical activity can modify the diabetes control are very topical.

The purpose of the research is to investigate the effect of regular aerobic physical exercises with 6-point intensity by Borg scale on glycemic profile, insulin sensitivity, and the quality of life (QL) of patients with type 1 diabetes mellitus.

Materials and methods

The data of 42 patients with type 1 DM were analyzed. There were 20 women and 22 men aged 18 to 35 years (mean age 25.3 ± 7.9 years). All patients included in the study had the compensated DM. Insulin therapy was administered with an ultra-short-acting insulin according to the dietary pattern and basal insulin.

The level of glycemia was measured 6 times a day — in the morning on an empty stomach, before and after aerobic exercise, and during the main meals.

Glycated hemoglobin (HbA1c) level was assessed on InnovaStar analyzer by immunoturbidimetric method. All patients included in the study performed aerobic exercises three times weekly.

The main requirements for physical activity were:
1) taking into account psychological characteristics of a patient;
2) all muscle groups must be involved;
3) no prolonged breaks and pauses;
4) duration 60 minutes or more;
5) energy expenditure at least 500 kcal per hour or more;
6) should be done in the morning.

According to these positions, the most convenient method to control the intensity of training was Borg scale. The main condition was individual and subjective load perception.

All subjects had moderate physical activity — 6 points by Borg scale, or 60.0–70.0 % of the highest possible heart rate. In this case, the simple and complex carbohydrates are the main resources for metabolism.

The team sports (25 patients) and swimming exercises (long, but not with maximum level, 17 patients) meet these requirements.

The Medical Outcomes Study Short Form 36 questionnaire (SF-36, developed and recommended by the International Center for Quality of Life Research) was used to assess the QL of patients. This questionnaire allows evaluating the subjective satisfaction of the patient with his physical and mental state, social functioning [11].

Patients were asked to fill the SF-36 questionnaire before the research and by the end of the controlled observation period. The SF-36 gives the opportunity to evaluate QL according to the eight scales: physical functioning (PF), role-physical functioning (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role-emotional functioning (RE) and mental health (MH) [11].

The patients had no previous history of smoking or drinking or gave up at least two weeks before the research. Dietary pattern included three main meals and two snacks.

Statistical analysis was performed using Statistica 7.0 (StatSoft, USA). Differences were statistically significant at p < 0.05.

Results

The clinical features of patients with type 1 DM before the study are presented in the Table 1.

After initial examination, the patients were included into prospective follow-up study (duration 25 to 37 days, the average of 32.50 ± 5.67 days).

The dynamics of ultra-short-acting insulin daily mean dose during controlled period is shown in Fig. 1.

The average insulin daily dose was calculated in accordance to individual observation chart for each patient during 2 weeks preceding the study and throughout the research period. As we can see, the mean daily dose of ultra-short-acting insulin was decreased from 35.1 ± 3.9 U to 28.00 ± 3.52 U (25.4 %, p < 0.05).

The basal bolus insulin doses did not change, with the mean of 19.20 ± 3.91 U/day. The bread units (BU) mean was 15.50 ± 2.71 and did not change before and after the study.

So, the sensitivity to insulin has significantly changed after regular aerobic exercises (Fig. 2).

Figure 1. Dynamics of ultra-short-acting insulin daily mean dose during controlled observation period

Note: here and in Fig. 2, 4: * — the significant changes (p < 0.05).

Figure 2. The sensitivity to insulin (UBU) in patients with type 1 DM during observation period
As we can see, the sensitivity to insulin after regular aerobic exercises increased by 42.0 % and was 0.60 U per 1 BU by the end of the observation versus 1.03 U per 1 BU at baseline.

According to the received data, regular morning aerobic exercises induce two episodes of glycemic curve lowering. So, the reduction of glucose level occurred during physical activity and immediately after it, which may be not only due to the direct glucose utilization in response to aerobic exercises, but also the result of lower glucose level throughout the day.

The daily glycemic profile and its dynamics are shown in Fig. 3.

Also, it was interesting to mark the delayed, more pronounced, intense and prolonged glucose level reduction 3–4 hours after physical activity.

HbA1c is an indicator of glycemic control level, marker of DM compensation and relevance of hypoglycemic therapy.

In our work, after 30 days of controlled observation and regular physical exercises, there was a significant decrease in the level of HbA1c that is shown in Fig. 4.

Thus, regular physical activity such as aerobic exercises in our study was associated with 1.5 % decrease in HbA1c.

During the first visit, SF-36 questionnaire [11] was also filled in.

The measuring model of the SF-36 has 3 levels: 1) the question; 2) eight scales, each of which consists of 2 to 10 points; 3) two aggregate measurements that combine the scales together. After analyzing the results, the answers have been received for all 36 items, which form 8 scales. Items are summed up and converted into values from 0 to 100 points, where 100 points is the maximum value, and 0 is the minimum. Higher scores represent the higher level of health.

The SF-36 includes one multi-item scale that assesses eight health concepts:
1. Physical functioning — limitations in physical activities because of health problems (self-service, walking, walking down the stairs, carrying weight, etc.).
2. Role limitation due to physical health is the influence of the physical state on the role functioning (work, daily activities).
3. Physical pain — the severity of pain and its impact on the ability to participate in everyday activities, including homework and out-of-home activities.
5. Role limitation due to emotional problems implies an assessment of the extent of the emotional state interfering with work or other daily activities (including high time expenditures, reduced scope of work, decrease in its quality, etc.).
6. Vital energy means a feeling of full strength and energy or, conversely, the weakness.
7. Mental health characterizes the mood (presence of depression, anxiety, a general indicator of positive emotions).
8. Social functioning is determined by the extent of social activity (communication) restriction due to the physical or emotional state.

Scales are grouped into two indicators like “physical component of health” and “psychological component of health”:

1. Physical health. Components of the scale: 1) physical functioning; 2) role-playing function conditioned by physical condition; 3) pain intensity; 4) general health.

Notes: the significant changes: p — between population index and patients with type 1 diabetes; p1 — in dynamics of observation.
II. Psychological health component. Components of the scale: 1) mental health; 2) role-playing function conditioned by the emotional state; 3) social functioning; 4) life activity. Each item was used to process score only by one of the scales.

On the basis of 8 scales, the total assessment of physical and mental health was performed. SF-36 results are presented in Table 2.

It was found that QL decreased in all patients with diabetes mellitus type 1 according to the all scales of SF-36 questionnaire. The lowest scores, when it was compared with the general population, were obtained on the scales of physical (PF, GH and RP) and psychological (RE, VT and SF) health components. Initial results indicate that physical and psychological health has a significant negative impact on routine activities.

The average indicators on the scales of role functioning conditioned by the emotional state, mental health, social functioning have shown that type 1 DM has a negative impact on the psychological component of health.

In the dynamics of treatment, it was found that the quality of life in patients with type 1 DM depends on the degree of glycemic compensation, as well as the level of physical activity. The reliable improvement of both physical and psychological components of health after regular morning aerobic exercises is proved.

Discussion

Physical activity is an important component of self-education that changes the level of compensation and quality of life in patients with type 1 DM. Physical activity leads to increased insulin sensitivity and activation of non-insulin-sensitive glucose transporters (GLUT-4). Thus, physical activity in patients with type 1 DM may affect glycemia during some hours. The decrease in glycemia is related to the divergence between production and utilization of glucose [3, 9].

This one affects the suppressing level of insulin. In healthy people, in response to physical activity, suppression of insulin secretion and increased glucose production by the liver are proved. In patients with type 1 DM, the level of insulin can be corrected only in advance, and counterregulatory mechanisms are disturbed or absent [5].

Decreased glycemia in this period requires the correction of insulin therapy. This can be achieved by reducing ultra-short-acting insulin dosage, which was confirmed in our study. The second way is lowering the basal insulin dosage, which has to be studied in future.

Low level of physical activity is also associated with poor quality of life [4], so this aspect should be included in the education programs (“Diabetic schools”) to improve the patient’s social activity and adaptation.

Conclusions

We have revealed the positive effect of regular aerobic exercises on the clinical symptoms of type 1 diabetes mellitus resulted in the improved glycemic profile, increased insulin sensitivity and quality of life.

1. It has been shown that aerobic exercises can significantly modify the clinical course of type 1 diabetes mellitus and change the quality of life.

2. After 30 days of regular aerobic exercises, the mean daily dose of ultra-short-acting insulin is decreased by 25.4 % versus baseline (p < 0.05).

3. The sensitivity to insulin after regular aerobic exercises increased by 42.0 % and became 0.60 U per 1 BU by the end of the observation versus 1.03 U per 1 BU before the study.

4. Regular physical activity was associated with the decrease in glycated hemoglobin level by 1.5 %.

5. Regular aerobic exercises contributed to a significant (p < 0.05) improvement of the quality of life by all the scales, which form physical and psychological components of health (PF, RP, BP, GH, RE, VT, MH, SF) versus baseline.

Клінічна ефективність аеробних фізичних навантажень у молодих пацієнтів із цукровим діабетом 1-го типу

Резюме. Мета дослідження: вивчити вплив регулярних аеробних фізичних навантажень інтенсивністю 6 балів за шкалою Борга на гликемічний профіль, чутливість до інсулу, а також якість життя у пацієнтів із цукровим діабетом (ЦД) 1-го типу. Матеріали і методи. Проаналізовано дані 42 пацієнтів із ЦД 1-го типу — 20 жінок та 22 чоловіків віком від 18 до 35 років (середній вік 25,3 ± 7,9 року). Рівень глюкемії оцінювався портативним методом 6 разів на день. Дослідження висвітлює гіпогликемію та гіпоглікемію, інтенсивність інсулинового шоку, якість життя. Чутливість до інсуліну зменшилася на 25,4 % від початкового рівня утром (р < 0,05). Сниження рівня глюкемії відбувається на 42,0 % (р < 0,05) та становила 1,50 ± 0,12 % (р < 0,05) на 1 час.

Виводи. Ключові слова: цукровий діабет 1-го типу; аеробні навантаження; гіпоглікемія; якість життя; чутливість до інсуліну; гіпоглікемія; гіпоглікемія.
